EXPERIMENT NO. 1

Design and Implementation of a Markov Decision Process (MDP) for a Simplified Chess Game

AIM

To design and implement a Markov Decision Process (MDP) for a simplified chess game using Python, where an intelligent agent learns the optimal sequence of moves by modeling board states, legal actions, transition probabilities, and reward functions to maximize the chances of winning the game.

OBJECTIVE

- Model a reduced chess-like board as a finite MDP with states, actions and rewards.
- Represent legal moves, transition probabilities and terminal (win/lose/draw) conditions.
- Solve the MDP using Value Iteration to obtain an optimal policy.
- Demonstrate the agent choosing optimal moves from any given board state.

THEORY

A Markov Decision Process (MDP) is a mathematical framework used to model sequential decision-making problems where outcomes are partly random and partly under the control of a decision-making agent. Formally, an MDP is defined by the tuple (S, A, P, R, γ) , where S is the set of states, A is the set of actions available in each state, $P(s'|s,a)$ is the transition probability of reaching state s' after taking action a in state s , $R(s,a,s')$ is the immediate reward received for that transition, and γ is the discount factor that determines how much future rewards are valued relative to immediate rewards.

Chess, in its full form, has an enormous state space, making it impractical for a lab-scale MDP. In this experiment we therefore model a simplified chess-like environment: a small board (for example a 4x4 grid) on which a single agent piece must navigate towards a goal square while avoiding squares controlled by an opposing piece, mimicking the notion of 'winning' by reaching the goal and 'losing' by being captured. Each board configuration (piece position, opponent position) is treated as a state. The legal moves of the piece (up, down, left, right, and diagonal moves as permitted) form the action set.

The transition function is largely deterministic in this simplified setting (a chosen move leads to a specific next state), but a small stochastic element can be introduced to represent uncertainty, such as the opponent piece moving randomly. The reward function assigns a large positive reward for reaching the goal (winning), a large negative reward for being captured (losing), and a small negative step-cost for every move to encourage the agent to win quickly rather than wander indefinitely.

The Bellman optimality equation $V^*(s) = \max_a \sum_{s'} P(s'|s,a)[R(s,a,s') + \gamma V^*(s')]$ characterizes the optimal value function for this MDP. Value Iteration repeatedly applies this equation to every state until the value function converges, after which the optimal policy is extracted by choosing, in every state, the action that maximizes the expected return. This experiment therefore illustrates how the abstract framework of MDPs can be applied to a game-like decision problem, forming the conceptual foundation for more advanced reinforcement learning algorithms covered in later experiments.

ALGORITHM

1. Define the board size and encode every (agent_position, opponent_position) pair as a unique state.
2. Define the action set: {UP, DOWN, LEFT, RIGHT} restricted to moves that stay on the board.
3. Define the transition function: applying an action moves the agent deterministically; the opponent moves one random legal step.
4. Define the reward function: +10 for reaching the goal cell, -10 for landing on the opponent's cell, -1 step cost otherwise.
5. Initialize the value function $V(s) = 0$ for all states.

6. Repeat until convergence (change in V below a small threshold θ): for every state s , compute $V(s) = \max_a \sum_{s'} P(s'|s,a)[R(s,a,s') + \gamma V(s')]$.
7. Extract the optimal policy $\pi^*(s) = \operatorname{argmax}_a \sum_{s'} P(s'|s,a)[R(s,a,s') + \gamma V(s')]$.
8. Simulate a game from the start state by following $\pi^*(s)$ until the goal or the opponent's cell is reached.

FLOW OF EXECUTION

1. Import libraries and define board dimensions, goal cell and reward constants.
2. Enumerate all valid states (agent_pos, opponent_pos combinations, excluding overlaps).
3. Build a lookup of legal actions per state and the resulting next-state distribution.
4. Run the Value Iteration loop, tracking the maximum value change per sweep for convergence checking.
5. Once converged, derive the greedy optimal policy for every state.
6. Simulate a play-through from a chosen start state, printing the board and move chosen at each step.
7. Print the final outcome (win/lose) and the total number of moves taken.

Result: Agent reached the goal. WIN!

```

EXPLANATION

- STATES enumerates every valid combination of agent and opponent positions, excluding overlapping cells.

- `step()` implements the transition function $P(s'|s,a)$: it returns all possible next states with their probabilities and rewards, capturing the stochastic movement of the opponent.
- `value_iteration()` repeatedly applies the Bellman optimality update until the value function changes by less than Θ , guaranteeing convergence to V^* .
- `extract_policy()` derives the optimal deterministic policy $\pi^*(s)$ by taking the argmax over actions of the expected return.
- `simulate()` plays out one episode using the learned policy, sampling the opponent's random response at each step, and reports the outcome.

TIME COMPLEXITY

$O(k * |S| * |A| * |S'|)$ for Value Iteration, where k is the number of sweeps to convergence, $|S|$ is the number of states ($O(n^4)$ for an $n \times n$ board), $|A|$ is the number of actions (4), and $|S'|$ is the branching factor of the opponent's random move (at most 5).

SPACE COMPLEXITY

$O(|S|)$ to store the value function and policy, i.e. $O(n^4)$ for an $n \times n$ board.

APPLICATIONS

- Turn-based strategy and board game AI (chess, checkers endgames, simplified game engines).
- Robotic path planning with a moving adversary or obstacle.
- Pursuit-evasion and pursuit-defense game modeling.
- Curriculum design for teaching MDP fundamentals before scaling to full RL algorithms.
- Security patrol-and-evasion simulations (abstracted as grid games).
- Foundation for building AlphaZero-style game engines using MDP formulations.

ADVANTAGES

- Provides an exact, mathematically guaranteed optimal policy (no approximation error).
- Simple to visualize and debug on a small board.
- Clearly demonstrates the core MDP concepts: states, actions, transitions, rewards.
- Extensible to more complex board sizes and opponent behaviors.
- Fast convergence for small state spaces.

LIMITATIONS

- Does not scale to real chess due to the astronomically large state space.
- Requires a fully known transition model, unlike model-free RL methods.
- Simplified opponent behavior (random moves) is unrealistic compared to a skilled adversary.

RESULT

A Markov Decision Process for a simplified chess-like game was successfully designed and solved using Value Iteration. The agent learned an optimal policy that guided it to the goal cell while avoiding the opponent piece, and the simulation confirmed that the agent consistently achieved a winning outcome from the given start state.

EXPERIMENT NO. 2

Reinforcement Learning Agent for a Smart Home Robot - Optimal Navigation via Agent-Environment Interaction

AIM

To develop a Reinforcement Learning agent for a smart home robot that learns optimal navigation through agent-environment interaction using Python.

OBJECTIVE

- Model a smart home as a grid environment with rooms, furniture obstacles and a charging-dock goal.
- Implement the agent-environment interaction loop (state, action, reward, next state).
- Train a tabular Q-Learning agent purely through trial-and-error interaction.
- Evaluate the learned navigation policy on unseen start positions.

THEORY

Reinforcement Learning (RL) is a paradigm in which an agent learns to make decisions by interacting with an environment, receiving feedback in the form of rewards, and adjusting its behaviour to maximize cumulative reward over time. The core interaction loop consists of the agent observing the current state s_t of the environment, choosing an action a_t according to its policy, receiving a reward r_t and the next state s_{t+1} from the environment, and using this experience to update its knowledge.

In this experiment, a smart home is represented as a grid where each cell corresponds to a location in the house (e.g. living room, kitchen, bedroom corridor), some cells are blocked by furniture (obstacles), and one cell represents the robot's charging dock (the goal). The robot's state is its current grid coordinate. Its actions are the four movement directions. This directly instantiates the agent-environment interaction loop that underlies all of reinforcement learning.

Q-Learning is a model-free, off-policy temporal-difference algorithm that learns the action-value function $Q(s,a)$, representing the expected cumulative reward of taking action a in state s and thereafter following the optimal policy. It does not require a known model of the environment's transition probabilities; instead, it learns purely from sampled experience. The update rule is $Q(s,a) \leftarrow Q(s,a) + \alpha[r + \gamma \max_{a'} Q(s',a') - Q(s,a)]$, where α is the learning rate and γ is the discount factor.

To balance exploring new actions against exploiting known good actions, an epsilon-greedy exploration strategy is used: with probability ϵ the agent picks a random action, and with probability $1-\epsilon$ it picks the action with the highest current Q-value. Over many episodes of agent-environment interaction, the Q-values converge towards the optimal action-values, allowing the robot to navigate the smart home to its charging dock along an efficient, obstacle-free path even from previously unseen starting rooms.

ALGORITHM

1. Represent the smart home as an $n \times n$ grid; mark obstacle cells and the goal (charging dock) cell.
2. Initialize $Q(s,a) = 0$ for all state-action pairs.
3. For each training episode: reset the robot to a random valid start cell.
4. For each step in the episode: choose action a using epsilon-greedy policy on $Q(s,.)$.
5. Execute action a , observe reward r and next state s' from the environment (obstacle collision penalty, goal reward, step cost).
6. Update $Q(s,a)$ using the Q-Learning update rule.
7. Set $s = s'$; repeat until goal reached or step limit exceeded.
8. Decay ϵ gradually across episodes to shift from exploration to exploitation.
9. After training, evaluate the greedy policy from several start states.

FLOW OF EXECUTION

1. Define the grid layout, obstacle positions and the goal (dock) position.
2. Initialize the Q-table as a dictionary keyed by (state, action).
3. Loop over episodes; within each episode loop over time steps performing the interaction cycle.
4. Track total reward per episode to visualize learning progress.
5. After training completes, freeze the policy (epsilon = 0) and run test navigations.
6. Print the path taken and total reward for each test run.

    for start in [(0, 0), (4, 0), (0, 4)]:
        path = navigate(start)
        print(f"Start {start} -> Path: {path}")

```

INPUT

5x5 smart home grid, obstacles at (1,1),(1,2),(3,3),(2,0), dock at (4,4)
 alpha=0.1, gamma=0.95, episodes=500, epsilon decays from 1.0 to 0.05

OUTPUT

Average reward, first 10 episodes : -124.20
 Average reward, last 10 episodes : 16.70

Start (0, 0) -> Path: [(0, 0), (0, 1), (0, 2), (0, 3), (1, 3), (1, 4), (2, 4), (3, 4), (4, 4)]
 Start (4, 0) -> Path: [(4, 0), (4, 1), (4, 2), (4, 3), (4, 4)]

Start (0, 4) -> Path: [(0, 4), (1, 4), (2, 4), (3, 4), (4, 4)]

EXPLANATION

- `step()` implements the environment's transition and reward function: wall/furniture collisions are penalised, reaching the dock gives a large reward, and every other move has a small step cost.
- `Q` is the tabular action-value function, initialised to zero and updated online after every interaction.
- `choose_action()` implements epsilon-greedy exploration, balancing trying new paths against exploiting the current best-known route.
- `train()` runs the full agent-environment interaction loop for many episodes, gradually decaying epsilon so the robot exploits more as it learns.
- `navigate()` evaluates the final greedy policy from a given start cell, tracing the shortest safe path the robot has learned to the dock.

TIME COMPLEXITY

$O(\text{episodes} * \text{max_steps})$ for training; $O(\text{path_length})$ for evaluating a single navigation run.

SPACE COMPLEXITY

$O(|S| * |A|)$ to store the Q-table, i.e. $O(\text{grid_size}^2 * 4)$.

APPLICATIONS

- Household service robots (vacuum cleaners, delivery robots) that must return to a charging station.
- Warehouse and factory floor robot navigation.
- Indoor drone path planning.
- Smart home automation systems that route robots around dynamic obstacles.
- Educational demonstration of the RL agent-environment interaction cycle.

ADVANTAGES

- Model-free: does not require prior knowledge of the environment's dynamics.
- Learns purely through interaction, matching how real robots gather experience.
- Simple tabular implementation that is easy to inspect and debug.
- Naturally handles obstacle avoidance through the reward signal.
- Converges to an optimal policy given sufficient exploration.

LIMITATIONS

- Tabular representation does not scale to large or continuous state spaces.
- Requires many episodes of interaction to converge, which can be costly in a real (not simulated) home.
- Sensitive to reward shaping; poorly designed rewards can lead to unwanted behaviour.

RESULT

A Q-Learning based Reinforcement Learning agent was successfully developed for a smart home robot. Through repeated agent-environment interaction, the robot learned an optimal navigation policy that reliably guided it from various starting rooms to its charging dock while avoiding furniture obstacles.

EXPERIMENT NO. 3

Design of a Markov Decision Process (MDP) for an Autonomous Warehouse Robot

AIM

To design a Markov Decision Process (MDP) for an autonomous warehouse robot by defining states, actions, transition probabilities, and reward functions.

OBJECTIVE

- Formally define the state space representing warehouse robot locations and shelf/pickup layout.
- Define the action space corresponding to the robot's movement and pick/drop operations.
- Specify a transition probability model, including a chance of wheel-slip stochasticity.
- Specify a reward function that encourages efficient item retrieval and delivery.

THEORY

An autonomous warehouse robot operates in a structured but dynamic environment consisting of aisles, shelves, a pickup point and a drop-off (packing) point. Formulating this problem as a Markov Decision Process allows the robot's decision-making to be framed rigorously as choosing actions that maximize expected long-term reward under uncertainty in its movement.

The state space S is defined as the Cartesian product of the robot's grid position and a binary flag indicating whether it is currently carrying an item, i.e. $s = (\text{row}, \text{col}, \text{carrying})$. This captures both 'where the robot is' and 'what task-stage it is in', which is essential because the optimal action can differ depending on whether the robot still needs to fetch an item or deliver one it already holds.

The action space $A = \{\text{UP}, \text{DOWN}, \text{LEFT}, \text{RIGHT}, \text{PICK}, \text{DROP}\}$ includes four movement actions and two task actions. PICK is only meaningful at the pickup shelf location, and DROP is only meaningful at the packing station. The transition probability function $P(s' | s, a)$ is mostly deterministic for movement actions but includes a small probability (e.g. 10%) of 'wheel slip', where the robot ends up in a different adjacent cell than intended, modeling real-world actuator noise on a warehouse floor.

The reward function $R(s, a, s')$ is designed to shape efficient behaviour: a small negative step cost (-1) is applied for every movement to encourage short paths, a moderate positive reward (+5) is given for a successful PICK at the shelf, and a large positive reward (+20) is given for a successful DROP at the packing station while carrying the item, which also ends the episode. Attempting PICK/DROP at the wrong location incurs a penalty. Together, (S, A, P, R, γ) fully specify the warehouse robot MDP, which can subsequently be solved with Dynamic Programming or model-free RL methods, as explored in later experiments.

ALGORITHM

1. Define grid dimensions and fixed locations: SHELF (pickup) and STATION (drop-off).
2. Define state as $(\text{row}, \text{col}, \text{carrying_flag})$; enumerate the full state space.
3. Define the six actions: UP, DOWN, LEFT, RIGHT, PICK, DROP.
4. For movement actions, define transition probabilities: 0.8 intended direction, 0.1/0.1 split to two perpendicular directions (slip model).
5. For PICK, transition deterministically sets $\text{carrying}=\text{True}$ only if at SHELF and not already carrying; else no state change with penalty.
6. For DROP, transition deterministically ends episode with high reward only if at STATION and carrying; else no state change with penalty.
7. Assign rewards for every (s, a, s') triple as per the reward specification.
8. Print the full formal MDP tuple (a sample of states/transitions) to document the design.

FLOW OF EXECUTION

1. Instantiate grid layout constants and print the warehouse map.
2. Programmatically enumerate all states and label terminal states.
3. Build the transition table $P(s'|s,a)$ including the stochastic slip probabilities for movement.
4. Build the reward table $R(s,a,s')$.
5. Display a sample of the MDP: a few example states, their legal actions, transition distributions and rewards, to verify the design.
6. Save/print the full MDP definition for use as input to the Dynamic Programming solver in Experiment 7.

```

EXPLANATION

- `all_states()` enumerates the full state space as (row, col, carrying), combining spatial location with the task-progress flag.
- `transitions()` encodes the transition probability function $P(s'|s,a)$: movement actions succeed with probability 0.8 and slip sideways with probability 0.1 each, while PICK/DROP are deterministic but only valid at specific locations.
- The reward constants (`STEP_COST`, `PICK_REWARD`, `DROP_REWARD`, `INVALID_TASK_PENALTY`) together define $R(s,a,s')$, shaping the robot towards efficient pickup-and-delivery behaviour.
- `is_terminal()` marks the episode as complete once the item has been dropped at the station.
- The sample state printout documents the MDP design, verifying that transition probabilities sum to 1 and rewards match the specification.

TIME COMPLEXITY

$O(1)$ to compute the transition outcomes for a single (state, action) pair; $O(|S| * |A|)$ to enumerate the full transition table for the whole MDP.

SPACE COMPLEXITY

$O(|S| * |A| * b)$ where b is the branching factor of stochastic outcomes (at most 3 here), for storing the full transition/reward tables.

APPLICATIONS

- Automated Guided Vehicles (AGVs) in warehouses and fulfilment centres.
- Robotic pick-and-place systems in e-commerce logistics.
- Hospital supply-delivery robots.
- Airport baggage-handling robot routing.
- Any pickup-and-delivery robotic task with actuator uncertainty.

ADVANTAGES

- Explicitly separates environment design (this experiment) from the solution algorithm, aiding clarity.
- Stochastic transition model realistically captures wheel-slip/actuator noise.
- Reward shaping cleanly encodes both efficiency (step cost) and task completion (pick/drop rewards).
- State representation (position + carrying flag) generalizes to multi-stage tasks.

LIMITATIONS

- Grid abstraction ignores continuous robot dynamics and multiple simultaneous obstacles.
- Single-item, single-robot assumption; does not model fleet coordination.

- Fixed slip probability may not reflect real sensor/actuator noise distributions.

RESULT

A complete Markov Decision Process was successfully designed for an autonomous warehouse robot, with clearly defined states, actions, stochastic transition probabilities and a reward function that together capture the pickup-and-delivery task, ready to be solved by planning or learning algorithms.

EXPERIMENT NO. 4

Implementation of Bellman Equations for an Autonomous Delivery Robot - Minimum Travel Cost Path

AIM

To implement Bellman equations for an autonomous delivery robot to determine the optimal path with minimum travel cost.

OBJECTIVE

- Model the delivery robot's environment as a weighted grid representing travel cost per cell.
- Implement the Bellman equation for the state-value function $V(s)$ via iterative updates.
- Compute the optimal policy by applying the Bellman optimality operator to convergence.
- Extract and display the minimum-cost delivery path from a start location to the destination.

THEORY

The Bellman equation is the central recursive relationship in Markov Decision Processes, expressing the value of a state in terms of the values of its successor states. For a given policy π , the Bellman expectation equation is $V_{\pi}(s) = \sum_a \pi(a|s) \sum_{s'} P(s'|s,a) [R(s,a,s') + \gamma V_{\pi}(s')]$. The Bellman optimality equation replaces the policy average with a maximization over actions: $V^*(s) = \max_a \sum_{s'} P(s'|s,a) [R(s,a,s') + \gamma V^*(s')]$, defining the value of behaving optimally from state s onward.

In this experiment, an autonomous delivery robot must travel across a grid city map from its depot to a customer's address. Each cell has an associated travel cost (representing distance, traffic, or terrain difficulty), and some cells may be impassable (blocked roads). The robot's goal is to find the path that minimizes total travel cost, which is equivalent to maximizing the negative cumulative cost (reward = -cost per move), with a large bonus reward for reaching the destination.

Applying the Bellman optimality equation iteratively (Value Iteration) to every state in this grid converges to the unique optimal value function $V^*(s)$, which represents the minimum expected cumulative cost from each cell to the destination. Once V^* is known, the optimal action in any state is simply the one that leads to the successor state with the highest value (equivalently, lowest remaining cost), i.e. $\pi^*(s) = \arg\max_a \sum_{s'} P(s'|s,a) [R(s,a,s') + \gamma V^*(s')]$.

This experiment demonstrates the direct, practical application of the Bellman equation as both a definition of optimality and a computational tool: by repeatedly 'backing up' value estimates through the recursive relationship, the delivery robot's full cost-minimizing route can be derived without ever explicitly enumerating all possible paths, which would be computationally infeasible on a large map.

ALGORITHM

1. Represent the city as a grid; assign a travel cost to every cell and mark blocked cells.
2. Define the reward for moving into a cell as the negative of its travel cost; assign a large bonus reward for the destination cell.
3. Initialize $V(s) = 0$ for all states.
4. Repeat: for every state s , update $V(s) = \max_a [R(s,a) + \gamma V(s')]$ using the Bellman optimality equation, where s' is the resulting cell of action a .
5. Stop when the maximum change in V across all states is below a small threshold.
6. Derive the optimal policy $\pi^*(s) = \arg\max_a [R(s,a) + \gamma V(s')]$ for every state.
7. Starting from the depot, repeatedly follow $\pi^*(s)$ to trace the minimum-cost path to the destination.
8. Sum the travel costs along the traced path to report the total minimum cost.

FLOW OF EXECUTION

1. Define the grid, per-cell travel costs and blocked cells.

2. Build the reward structure using negative travel costs plus a destination bonus.
3. Run the Bellman-equation-based value iteration loop until convergence, logging the delta each sweep.
4. Extract the greedy optimal policy from the converged value function.
5. Trace the path from the depot to the destination by following the policy.
6. Print the path, the value function map, and the total minimum travel cost.

    path, total_cost = trace_path(policy)
    print(f"Optimal minimum-cost path from {DEPOT} to {DESTINATION}:")
    print(" -> ".join(str(p) for p in path))
    print(f"Total travel cost: {total_cost}")

```

INPUT

5x5 grid, depot=(0,0), destination=(4,4), blocked=(1,2),(2,2),(3,1)
 heavy-traffic cell (2,3) cost=4, rough-terrain cell (1,4) cost=3, all other cells cost=1

OUTPUT

Bellman value iteration converged in 9 sweeps.

Optimal minimum-cost path from (0, 0) to (4, 4):
 (0, 0) -> (1, 0) -> (2, 0) -> (3, 0) -> (4, 0) -> (4, 1) -> (4, 2) -> (4, 3) -> (4, 4)
 Total travel cost: 8

EXPLANATION

- COST defines the per-cell travel cost that determines the negative reward for entering each cell, including two deliberately expensive cells to force a non-trivial optimal route.
- `next_state_reward()` implements one application of the transition/reward function used inside the Bellman equation.
- `value_iteration()` repeatedly applies the Bellman optimality equation $V(s) = \max_a [R + \gamma V(s')]$ across all states until the values stabilize ($\delta < \text{THETA}$).
- `extract_policy()` reads off the optimal action per state directly from the converged value function.
- `trace_path()` follows the greedy policy from the depot to the destination, accumulating the true travel cost of the resulting route, confirming it avoids the expensive and blocked cells.

TIME COMPLEXITY

$O(k * |S| * |A|)$ for value iteration, where k is the number of sweeps to convergence and $|S| = \text{grid_rows} * \text{grid_cols}$.

SPACE COMPLEXITY

$O(|S|)$ to store the value function and policy.

APPLICATIONS

- Last-mile delivery robot and drone route planning.
- GPS navigation systems computing minimum-cost/time routes.
- Autonomous forklifts and AGVs in cost-weighted factory floors.
- Network routing where 'cost' represents latency or congestion.
- Ride-sharing and logistics fleet routing under variable road costs.

ADVANTAGES

- Guarantees a globally optimal path with respect to the defined cost model.
- Bellman-equation-based approach handles arbitrarily shaped cost landscapes, not just uniform grids.
- Naturally incorporates blocked/impassable regions.
- Easily extended to stochastic transitions if actuator noise is present.

LIMITATIONS

- Requires the full cost map to be known in advance (not learned online).
- Grid discretization may not capture real road network topology precisely.
- Computational cost grows with grid size, becoming expensive for very large maps.

RESULT

The Bellman optimality equation was successfully implemented via Value Iteration for an autonomous delivery robot, and the resulting optimal policy produced a minimum-cost path from the depot to the destination that correctly avoided blocked and high-cost cells.

EXPERIMENT NO. 5

Epsilon-Greedy Multi-Armed Bandit Algorithm for an Online Advertisement Recommendation System

AIM

To implement the epsilon-greedy Multi-Armed Bandit algorithm for an online advertisement recommendation system to maximize user engagement through balanced exploration and exploitation.

OBJECTIVE

- Model each candidate advertisement as an 'arm' of a multi-armed bandit with an unknown click-through rate.
- Implement the epsilon-greedy action-selection strategy to balance exploration and exploitation.
- Estimate the click-through rate of each ad using incremental sample-average updates.
- Evaluate cumulative reward and identify the best-performing advertisement over time.

THEORY

The Multi-Armed Bandit (MAB) problem is a classical reinforcement learning formulation in which an agent must repeatedly choose among several actions ('arms'), each yielding a stochastic reward from an unknown distribution, with the goal of maximizing total reward over time. Unlike full MDPs, bandit problems involve no notion of state transition -- each decision is independent -- making them ideal for modeling single-shot recommendation decisions such as which advertisement to display to a user.

In an online advertisement recommendation system, each advertisement can be modeled as a bandit arm, and 'pulling' an arm corresponds to displaying that ad to a user. The reward is binary: 1 if the user clicks the ad, 0 otherwise. The true click-through rate (CTR) of each ad is unknown and must be estimated from observed clicks. The central challenge is the exploration-exploitation trade-off: the system must explore lesser-shown ads to gather information about their true CTR, while also exploiting the ad currently believed to have the highest CTR to maximize immediate engagement.

The epsilon-greedy algorithm addresses this trade-off simply and effectively: with probability epsilon, the system selects a uniformly random ad (exploration); with probability 1-epsilon, it selects the ad with the highest current estimated CTR (exploitation). The estimated value $Q(a)$ of each arm is updated incrementally after every observation using $Q(a) \leftarrow Q(a) + (1/N(a)) * (\text{reward} - Q(a))$, where $N(a)$ is the number of times arm a has been selected so far. This incremental sample-average formulation avoids storing the full reward history.

Over many rounds of user interaction, the epsilon-greedy strategy allows the recommendation system's CTR estimates to converge towards the true CTRs, while still delivering good average engagement throughout the learning process because exploitation dominates action selection whenever epsilon is kept small. This experiment demonstrates the bandit formulation and epsilon-greedy solution as a lightweight, effective foundation for real-world ad recommendation and A/B testing systems.

ALGORITHM

1. Define the set of candidate advertisements (arms) and their true (hidden) click-through rates for simulation purposes.
2. Initialize the estimated value $Q(a) = 0$ and count $N(a) = 0$ for every arm a .
3. For each round (simulated user visit): generate a random number; if less than epsilon, select a random arm (explore); otherwise select $\text{argmax}_a Q(a)$ (exploit).
4. Simulate the user's response: reward = 1 with probability equal to the chosen arm's true CTR, else 0.
5. Increment $N(a)$ for the chosen arm and update $Q(a)$ using the incremental sample-average update rule.
6. Record the reward for computing cumulative and average reward statistics.
7. Repeat for a fixed number of rounds.

8. Report the final estimated CTR per ad, the number of times each was shown, and the best-performing ad identified.

FLOW OF EXECUTION

1. Define the ads and their true (unknown-to-agent) click-through rates for simulation.
2. Initialize Q and N arrays for all arms.
3. Loop over simulated rounds performing epsilon-greedy selection, simulated click, and Q-value update.
4. Track cumulative reward and rolling average reward across rounds.
5. After all rounds, print final CTR estimates versus true CTRs and the recommended best ad.

PYTHON PROGRAM

```

"""
Experiment 5: Epsilon-Greedy Multi-Armed Bandit for Online Ad Recommendation.
Simulates a stream of user visits where the system must choose which
advertisement to show, balancing exploration (trying ads to learn their
CTR) with exploitation (showing the ad believed to have highest CTR).

Total rounds simulated : 5000
Total clicks obtained : 686
Overall CTR achieved : 0.1372

Ad	True CTR	Estimated CTR	Times Shown
Ad_A	0.05	0.0284	211
Ad_B	0.12	0.1152	217
Ad_C	0.09	0.0824	279
Ad_D	0.15	0.1472	4293

Best advertisement identified by the agent: Ad_D

EXPLANATION

- TRUE_CTR represents the ground-truth click probabilities that are unknown to the agent and are only used by simulate_click() to generate realistic user feedback.
- epsilon_greedy() implements the core algorithm: with probability EPSILON it explores a random ad, otherwise it exploits the ad with the current highest estimated Q-value.
- The incremental update $Q[ad] += (\text{reward} - Q[ad]) / N[ad]$ computes a running sample average of observed rewards without storing full history, which is memory-efficient.
- After 5000 rounds, the estimated CTRs closely match the true CTRs, and the agent correctly identifies Ad_D as the best-performing advertisement, showing it far more often than the others.
- The overall achieved CTR (0.1234) is close to the true CTR of the best ad (0.15), demonstrating the trade-off cost of the exploration phase.

TIME COMPLEXITY

$O(\text{rounds} * |\text{ADS}|)$ in the worst case for the max operation each round; effectively $O(\text{rounds})$ since the number of ads is small and constant.

SPACE COMPLEXITY

$O(|\text{ADS}|)$ to store Q and N estimates for each arm.

APPLICATIONS

- Online advertisement and content recommendation systems.
- A/B and multivariate testing of website designs or marketing copy.
- Dynamic pricing and promotional offer selection.

- Clinical trial arm allocation (adaptive trial design).
- News article and video recommendation ranking.
- Personalized email subject-line optimization.

ADVANTAGES

- Extremely simple to implement and computationally lightweight.
- Requires no knowledge of reward distributions in advance.
- Naturally balances exploration and exploitation via a single tunable parameter.
- Converges to the best arm given sufficient rounds.
- Widely applicable to any 'choose one of several unknown options' problem.

LIMITATIONS

- Fixed epsilon continues to explore sub-optimal ads even after the best ad is well identified, wasting some engagement.
- Does not use confidence bounds, so exploration is not directed towards the most uncertain arms (unlike UCB).
- Assumes stationary click-through rates; performs poorly if user preferences drift over time.

RESULT

The epsilon-greedy Multi-Armed Bandit algorithm was successfully implemented for an online advertisement recommendation system. Over 5000 simulated rounds, the algorithm's estimated click-through rates converged close to the true rates and correctly identified the highest-CTR advertisement, demonstrating effective balancing of exploration and exploitation.

EXPERIMENT NO. 6

Reinforcement Learning Model for Autonomous Robot Navigation using OpenAI Gym, TensorFlow/Keras and Python

AIM

OUTPUT

Comparing adaptation speed on a brand-new task (target slot 5):

From scratch (zero-init)	after 2 fine-tune episodes -> path=[0, 1, 2, 1, 2, 1, 2, 1, 2], reward=None
Meta-initialized (Reptile)	after 2 fine-tune episodes -> path=[0, 1, 2, 3, 4, 5], reward=10

Comparing on a second new task (target slot 2):

From scratch (zero-init)	after 2 fine-tune episodes -> path=[0, 1, 2], reward=10
Meta-initialized (Reptile)	after 2 fine-tune episodes -> path=[0, 1, 2], reward=10

RESULT: Program executed successfully and the desired output was verified.

```

INPUT

5x5 grid, goal=(4,0), obstacles={(1,0),(1,1),(3,3)}, gamma=0.9
Value Iteration until convergence (theta=1e-4)

OUTPUT

Bellman optimality equation converged in 7 sweeps.

Optimal state-value function $V^*(s)$ (row by row):

1.96	3.29	4.76	3.29	1.96
OBS	OBS	6.40	4.76	3.29
12.50	10.25	8.22	6.40	4.76
15.00	12.50	10.25	OBS	6.40
0.00	15.00	12.50	10.25	8.22

Optimal path from (0,4) to goal (4, 0):

(0, 4) -> (1, 4) -> (2, 4) -> (3, 4) -> (4, 4) -> (4, 3) -> (4, 2) -> (4, 1) -> (4, 0)

RESULT: Program executed successfully and the desired output was verified.

EXPERIMENT NO. 29**Dynamic Programming Solution to Optimize Traffic Light Timings at an Intersection****AIM**

    print(f"Average daily reward (first 100 episodes): {sum(rewards[:100]) / 100:.2f}")
    print(f"Average daily reward (last 100 episodes) : {sum(rewards[-100:]) / 100:.2f}")

    print("\nLearned admission policy:")
    for free_beds in range(MAX_BEDS + 1):
        for urgency in range(3):
            state = (free_beds, urgency)
            action = max(ACTIONS, key=lambda a: Q[state][a])
            print(f"    free_beds={free_beds}, urgency={urgency} -> {action}")

```

INPUT

Ward with max_beds=5, patient urgency levels {0,1,2}, actions={ADMIT,DEFER}
 Q-learning, alpha=0.15, gamma=0.9, episodes=2000

OUTPUT

Average daily reward (first 100 episodes): 6.63
 Average daily reward (last 100 episodes) : 69.89

Learned admission policy:
 free_beds=0, urgency=2 -> DEFER
 free_beds=1, urgency=2 -> ADMIT
 free_beds=2, urgency=1 -> ADMIT
 free_beds=5, urgency=0 -> ADMIT
 (full policy table printed for all free_beds x urgency combinations)

RESULT: Program executed successfully and the desired output was verified.

EXPERIMENT NO. 40**Reinforcement Learning for Personalized Educational Experiences in Online Learning Platforms****AIM**

Apply reinforcement learning techniques to personalize educational experiences for students in online learning platforms or intelligent tutoring systems. Develop a simulation environment that models student learning dynamics, curriculum content, and teaching interventions, and use reinforcement learning algorithms to learn policies that adaptively tailor educational content and interventions to individual student needs and preferences. Write a Python program to simulate the educational processes and evaluate the personalized learning policies.

PYTHON PROGRAM

```

"""
Experiment 40: Apply RL to personalize educational experiences for
students in an online learning platform. The agent chooses the
difficulty level of the next question/lesson to maximize student
learning gain while avoiding frustration (too hard) or boredom (too
easy). State = (student_skill_level, last_result); Actions = EASY,
MEDIUM, HARD content.
"""

MODEL QUESTION PAPER

MLA03 - Reinforcement Learning

Time: 3 Hours

Max. Marks: 100

Answer ALL questions from Part A. Answer any FIVE questions from Part B.

PART - A (10 x 2 = 20 Marks)

Answer ALL Questions

1. Define a Markov Decision Process (MDP) and list its five components.
2. What is the Bellman optimality equation? Write its mathematical form.
3. Differentiate between exploration and exploitation with an example.
4. What is the exploration-exploitation trade-off in the epsilon-greedy Multi-Armed Bandit algorithm?
5. Distinguish between Policy Iteration and Value Iteration.
6. What is the difference between Monte Carlo methods and Temporal-Difference (TD) methods?
7. Differentiate on-policy learning (SARSA) from off-policy learning (Q-Learning).
8. What is a Deep Q-Network (DQN), and why is experience replay used in it?
9. Define Partially Observable Markov Decision Process (POMDP) and state one real-world application.
10. What is the role of the discount factor (γ) in a Markov Decision Process?

PART - B (5 x 16 = 80 Marks)

Answer any FIVE Questions

1. (a) Explain the components of a Markov Decision Process in detail with a suitable example. (b) Derive the Bellman expectation equation and the Bellman optimality equation for the state-value function.
2. Explain the Value Iteration algorithm in detail. Illustrate with an example how it converges to the optimal policy for a grid-world navigation problem.
3. (a) Explain the epsilon-greedy algorithm for the Multi-Armed Bandit problem. (b) Compare epsilon-greedy, Upper Confidence Bound (UCB), and Thompson Sampling strategies for balancing exploration and exploitation.
4. Explain the Q-Learning algorithm in detail, including its update rule. Discuss how it differs from SARSA with a comparative example.
5. (a) Explain the architecture and working of a Deep Q-Network (DQN). (b) Explain the concepts of Double DQN, Dueling DQN, and Prioritized Experience Replay, and how each improves upon standard DQN.
6. Explain the REINFORCE algorithm in detail with its policy-gradient update rule. Discuss the role of a baseline in reducing variance.
7. (a) Explain the Actor-Critic architecture and how it combines value-based and policy-based methods. (b) Differentiate between A2C and A3C.
8. Explain the Proximal Policy Optimization (PPO) algorithm, including the clipped surrogate objective. Compare it with Trust Region Policy Optimization (TRPO).
9. (a) Explain Hierarchical Reinforcement Learning and the MAXQ task-decomposition framework. (b) Explain the concept of Multi-Agent Reinforcement Learning (MARL) with a cooperative-task example.
10. Explain the concept of a Partially Observable Markov Decision Process (POMDP). Describe how belief-state tracking (Bayesian filtering / particle filtering) allows an agent to act under uncertainty.
